The VM configuration file stores the number of processors, the number of virtual processors, and the initial OS stack size. The former is used to determine the maximum amount of processor time available to the virtual machine (the latter two parameters are only useful if you are running on an N-1 hyperthreading system). The additional OS stack size value is used to set the initial size of the process' own stack and to prevent the virtual machine from accessing another process' memory area by jumping into it on the stack. In some cases the contents of the UnixStacksize parameter can be used to create a named pipe (via dup2(1)) and have the virtual machine send its name to it via a select loop. The virtual machine can then connect to this pipe with a call to open(). This feature is enabled by default, but if your virtual machine needs to make system calls to communicate with the outside world it should be disabled. The VM snapshot provides a means for creating an exact snapshot of a virtual machine's current state. By default snapshots are saved and restored at startup. Snapshots may also be saved manually as well, and they are useful for creating reusable backup images or for temporarily booting a virtual machine. The JVM and Java language are widely accepted as a popular choice for virtual machines. At this time, the Oracle Corporation provides the open source version of the HotSpot VM with the standard JVM libraries. Although the Java language's features described above provide significant protection against many common programming mistakes, nothing can protect against all programming errors. The language and compiler are effective at preventing common exploits, and Java 6u7 compiles the Java programs to binaries that are very difficult to tamper with. However, there are few use cases where the standard Java language is the best choice.

During VM execution, the virtual machine may modify the process memory image, and the attacker may be able to corrupt the code or data of other processes. Some vulnerabilities can be exploited by loading an external data file into a process. The Java language offers a number of mechanisms that improve the performance of Java programs. The API for object-oriented programming, java.lang, contains efficient implementation of methods that most Java programs will use frequently. The Java Virtual Machine [5] provides a secure sandbox for java apps; this prevents malicious programs from directing a user to a dangerous site or bypassing other security checks. The Java Language Specification provides a version-independent, clear specification of Java language constructs. The Java Runtime Environment [6] provides the classes necessary for the execution of a Java program; the classes in this package support the creation of threads, synchronization, and input and output. These mechanisms make Java code easier to write and faster to execute. The language provides tools to aid the programmer in ensuring that their code is correct. At compile time, a Java compiler checks that the code follows the rules of the type system and that values are the correct type for their operation. At run time, the virtual machine provides type-safety. The run-time environment prevents programs from violating the specification by ensuring that every thread of execution in a Java program runs within the security of the sandbox. A virtual machine may also prevent an unsafe method implementation from executing code. This is done by creating a new virtual method that invokes the method being called. If the object checks that the method is safe to execute, it will not run the method, but it will also not throw an exception. 5ec8ef588b
